From Today’s City to Tomorrow’s City: An Empirical Investigation of Urban Land Assembly

December 2013

Because urban areas are fundamentally constrained by the boundaries of land ownership, economic and technological shocks cannot modify the urban landscape without also changing the delineation of land. In this paper, we ask if urban land markets are capable of producing such changes in land delineation. Specifically, we test if there is enough land assembly — the legal joining together of two or more parcels of land — to put land to its highest value use. Failure to assemble land may reduce agglomerative benefits, produce urban blight, push growth to the city edge and away from the core; ultimately it may cause cities to forfeit economic growth. We develop a simple theoretical framework which provides a testable hypothesis: in the absence of market frictions, the price of land sold for assembly should not exceed the price of land sold for other uses. This hypothesis does not hold when frictions, such as holdouts and land use regulation, drive the market for land assembly. We test this hypothesis using a novel dataset that follows each of the 2.3 million parcels in Los Angeles County over a twelve year period and allows us to observe all instances of assembly. Using panel data methods, we find that to-be-assembled land trades at a 40 percent premium. Thus, we find that urban land markets are subject to significant frictions that prevent assemblies and produce sclerotic urban redevelopment. Additional empirical results suggest that private market frictions, such as holdouts, play an important role in blocking assembly.

The analysis and conclusions set forth are those of the authors and do not indicate concurrence by the Board of Governors of the Federal Reserve. We are extremely grateful to staffers Bulmaro Borrero, Rex Hartline, and Alan Santos at the Los Angeles County Assessors office for providing data and guidance while we endlessly assembled the dataset for this paper. We are also appreciative to the Lincoln Institute for Land Policy, McGill University and the John Randolph Haynes and Dora Haynes Foundation, all of which contributed funds towards the construction of the dataset (before Brooks began at the Federal Reserve Board). We thank Gustavo Bobonis, Edward Coulson, Richard England, Lynn Fisher, Edward Glaeser, Robert Inman, Jeffrey Lin, Dan McMillen, Raven Molloy, Kathy O’Regan, Vasia Panousi, Jaren Pope, Hui Shan, William Strange, David Wildasin and participants at the 2010 and 2011 International American Real Estate and Urban Economics Association conferences, 2010 Federal Reserve System Regional Analysis conference, 2010 Lincoln Institute conference (October), 2010 National Tax Association Annual Conference, 2011 ASSA meetings, 2011 Lincoln Institute Urban Economics and Public Finance Conference (May), 2011 NBER Summer Institute (Law and Economics & Economics of Real Estate and Local Public Finance), 2011 Planning Law and Property Rights (Alberta), the Philadelphia Federal Reserve, the Federal Trade Commission, the Urban Institute, the University of Michigan Economics Department, the University of Toronto Economics Department, and the Federal Reserve Board of Governors. We are very grateful to the planners and developers that shared insights with us and greatly improved the paper; they are listed in the bibliography. This paper would not exist but for the superior research assistance of Brian McGuire.
Cities are composed of individual pieces of land called parcels. Just as atoms dictate the properties of matter, parcels dictate the size, shape and placement of the built infrastructure of which cities are composed. Changes in technology and economic conditions cannot induce fundamental changes to this built infrastructure without changes to parcel boundaries. Thus, the long-run evolution of cities – and the economic growth and innovation they generate – depends upon the ease of modifying parcel boundaries.

Changes to parcel boundaries within a city usually involve the assembly of multiple individually-owned parcels into one larger, singly-owned parcel — a process called land assembly. Because land assembly requires geographic contiguity, an individual parcel owner has a form of monopoly power when his neighbor wishes to assemble land (Merrill, 1986). Does this monopoly power create economically meaningful frictions? In this paper we address this question by testing whether the market produces enough assemblies to put land to its highest value use. In doing so, we estimate what is, to the best of our knowledge, the first overall premium to land assembly.

Theorists, economic historians, and practitioners all argue that market imperfections yield “too little” land assembly – and that this failure can hinder economic growth. Whether due to inefficiencies from asymmetric information (Strange, 1995), or positive externalities arising from assembly (Grossman and Hart, 1980; O’Flaherty, 1994), theorists argue that holdout behavior is likely to prevent profitable assemblies.¹ Economic historians contend that the ability to assemble ownership interests is often a crucial pre-requisite for economic growth, citing examples as diverse as how fragmented powers of eminent domain in pre-Revolutionary France inhibited profitable irrigation projects (Rosenthal, 1990), and how the land subdivision boom of the 1920s caused subsequent problems of land assembly and

stagnation in the 1930s (Field, 1992). Practitioners, such as urban planners, concur with this dour assessment and call land assembly the “single biggest obstacle to central city redevelopment” (Nelson and Lang, 2007).

If land cannot be assembled in sufficient quantity, cities will fail to adjust to new economic realities. Most significantly, land assembly allows cities to become denser. Market frictions which inhibit assembly therefore cause land to be misallocated to sub-optimally dense uses. Moreover, cities exist largely because they yield agglomeration effects—i.e., external economies of scale—and these benefits increase with density (Duranton and Puga, 2004; Rosenthal and Strange, 2004). Insufficient land assembly, by restraining density, reduces the magnitude of agglomerative effects. Cities which fail to redevelop at the center due to problems with land assembly may instead expand at the edge, yielding congestion and attendant environmental ills (Miceli and Sirmans, 2007). Moreover, problems of land assembly may cause cities to turn to eminent domain: nearly seventy percent of legally contested eminent domain cases involve land which has been seized for use in a land assembly (Merrill, 1986).

“Too little” land assembly also has important consequences for how economists think about cities. The canonical model of urban redevelopment posits that land is redeveloped when the present value of the capital situated on it is exceeded by the present value of redevelopment. If land assembly is required for capital adjustment, but assembly is blocked

---

\(^2\)Bogart and Richardson (2009) contend that the British Parliament’s willingness to “assemble” ownership interests in land following the Glorious Revolution of 1688 yielded dividends in economic growth. Rosen suggests that problems of land assembly inhibited redevelopment even after very large shocks, such as the Great Chicago Fire of 1871 (Rosen, 1986). Relatedly, differences in systems of land demarcation across the U.S. states (Libecap and Lueck, 2011) and across former British colonies (Libecap et al., 2010) yield divergent economic outcomes. Finally, legal scholars such as Heller (1998) argue that problems of land assembly helped to inhibit redevelopment in Eastern Europe.

\(^3\)For instance, as cities grow in population, more capital intensive use of the land is optimal (Henderson, 1977). The inability to assemble land impedes this population driven evolution toward a denser city.

\(^4\)The recent *Kelo v. City of New London* case (545 U.S. 469 (2005)), in which the city of New Long used its power of eminent domain to assemble land that it then provided to a private developer, brought these issues into focus.

by market frictions, capital decay alone is insufficient to generate redevelopment.

Finally, understanding if and why the market fails to produce land assembly also helps us to understand how the more general problem of fragmented ownership – the “tragedy of the anticommons” – may impede efficient outcomes (Heller, 1998; Fennell, 2004). Other problems of fragmented ownership include the resolution of sovereign debt consolidations (Pitchford and Wright, 2008), and the efficient use of multiple related patented discoveries (Heller and Eisenberg, 1998).

We begin with a simple theoretical framework that considers an area where the parcel boundaries, set at the time of initial development, are no longer optimal. Specifically, we assume that the per square foot price of a large parcel has come to exceed the price of a small parcel (motivated by the greater range of uses available for larger parcels). As a result, there is an economic incentive to assemble land. We also assume free entry into the market for assembly and that, correspondingly, developers earn zero profits and all surplus from assembly goes to the landowners who sell into an assembly. This framework yields the following testable assertion: in a market free of frictions, the price of land sold for assembly should not differ from the price of land sold for other purposes. In a competitive market, any differences in the land price per square foot should be arbitraged away. This test is similar in spirit to Glaeser et al. (2005).

To evaluate this contention we require a method to value land in isolation from any capital which may be situated on it. We rely on the technique pioneered by Rosenthal and Helsley (1994) and refined by Dye and McMillen (2007) that identifies the price of land from parcels sold when the structure is subsequently torn down. Because the structure is worthless to the new owner, the sale value represents only the land value. We compare the price of properties sold as “teardowns” to properties sold for assembly, conditional on small neighborhood (tract or block group) fixed effects that net out the main component of land empirical work.
value: location.

For our empirical work, we construct what is, to the best of our knowledge, the most appropriate existing dataset for this question. We have assembled a panel dataset that traces each of the 2.3 million parcels in Los Angeles County over an 11-year period from 1999 to 2011. The dataset is based on annual cross-sections containing all parcels in the county and a database, provided by the County Assessor, which identifies all instances of changes to parcel boundaries and links each parcel that ceases to exist with its descendant. Our dataset allows us to follow each individual piece of land in the county over this entire period.

We find that assembly land sells at a 40 percent premium relative to non-assembly land. We show that this premium is not likely driven by the endogenous location of assembly by using a falsification check for the impact of assembly on the neighborhood pre-assembly, and a repeat sales specification. We establish that our results are not driven by owners’ subjective valuations of their properties (i.e., high reservation prices), by considering the premium by property use and by owner occupancy. Taken together, we interpret our results as evidence that the market for land assembly is subject to substantial frictions.

The frictions we document could result from imperfections in both the public and private spheres. Public frictions arise from the regulation of land by local governments, such as zoning restrictions, development fees, and building codes (Glaeser et al., 2005). Private market failures stem from bargaining problems between the developer of the assembled land and the land sellers, causing problems such as holdouts. To establish whether private market frictions are an important part of the problem, we perform two additional tests motivated by theoretical conjectures about the relationship between parcel size and both assembly probability and the sales price of assembled parcels. We find suggestive evidence that private market imperfections are substantial.
1 Theoretical Framework

1.1 Surplus to Assembly

We begin our analysis with a simple theoretical framework that generates testable predictions about land assembly. Assume that at the time of initial development, time $t - j, j > 0$, land is developed into parcels of size $a$ and $2a$. The relative quantities of the different sized parcels are chosen optimally given market conditions at time $t - j$ such that the per-square foot price of parcels size $a$ and size $2a$ is equal. As time passes, those initial parcel definitions may become sub-optimal. In this vein, we assume that by time $t$, market conditions have evolved such that larger parcels size $2a$ command a premium relative to smaller parcels sized $a$. In other words, the relationship between land value and parcel size has become convex, such that $V(2a) > 2V(a)$ where $V(x)$ is the market price of a parcel of size $x$. Consistent with our empirical approach, which focuses on the value of land and not capital, we assume that any capital placed on the land at time $t - j$ has depreciated to zero by time $t$. Figure 1a graphically presents the convexity of the land price function, $V$. The price per unit $a$ of land increases with the size of the parcel. (In contrast, the thin dashed line, ending at $2V(a)$, illustrates a linear land value function where the price per unit $a$ of land is constant.)

Land values tend to become convex when the optimal capital to land ratio increases. Convexity arises because the density implied by high capital to land ratios requires large lots. For example, taller buildings typically require larger footprints. Similarly, builders may require large lots in order for buildings to be of sufficient size to absorb fixed costs such as elevators.

The optimal capital to land ratio in a metropolitan area may increase for any number of reasons. Population growth tends to increase the optimal capital to land ratio (Henderson, 1977). Similarly, increased commute times in an urban area may push the optimal ratio up in the urban core. The optimal ratio may also rise when land use shifts geographically with time.
For instance, land initially developed into small single family lots may eventually become more valuable for commercial purposes. Commercial uses typically imply a higher capital to land ratio, and thus larger lot sizes. Finally, technological shocks may also change this ratio. For example, Willis (1995) describes how the invention of fluorescent lighting changed the shape of office buildings and thus increased the optimal lot size for such buildings.

The convexity in the land value function implies that assembly generates a surplus relative to maintaining existing parcel boundaries. We define surplus value, $s$, as

$$s = V(2a) - \delta - 2V(a),$$  \hspace{1cm} (1)

where $\delta$ is the cost of assembly and captures factors such as conversion costs (e.g., demolition, grading to-be assembled parcels with different slopes, etc.) and “good-institution” transactions costs. Crucially, $\delta$ only includes costs which would reasonably arise in a well-functioning land market free of frictions. We use the term “good-institution” to sharply distinguish transactions costs consistent with a well-functioning land market from “bad-institution” transactions costs better viewed as frictions. “Bad-institution” transactions costs might include holdouts. For example, $\delta$ includes the cost of changing title to a property, but not delays to change in title caused by protesting neighbors.

Convexity in the land price function is a necessary condition for land assembly to occur (Shoup, 2008). The cost of assembly, $\delta$, can only be covered when the value of the assembled parcel, $V(2a)$, exceeds the value of the unassembled parcels, $2V(a)$. The value of the unassembled parcels, $2V(a)$, is the opportunity cost of assembly; it represents the economic returns to the unassembled land foregone in exchange for realizing the higher return to the assembled land.

In a frictionless world, arbitrage ensures that all surplus is realized and that assemblies continue until the market price of land has adjusted such that any surplus is eliminated.
Specifically, as assemblies occur the supply of lots sized $2a$ expands and the price of these lots falls. Assembly ceases when the return to assembled and unassembled lots has equalized: $V(2a) - \delta = 2V(a)$ and $s = 0$. Figure 1b—a supply and demand graph for parcels sized $2a$—displays this process. For simplicity, we assume that the quantity of parcels sized $a$ is arbitrarily large relative to the demand for parcels sized $2a$. As a result, $V(a)$ is fixed and the supply curve for parcels sized $2a$ is horizontal at the marginal cost of producing such parcels, $2V(a) + \delta$. In the absence of frictions, the market will assemble land until there are $q'$ parcels sized $2a$. When the market reaches equilibrium following the period of assembly activity, the land value function has flattened out from $V$ to $V'$ in Figure 1a and the price difference between parcels sized $a$ and $2a$ is the cost of assembly, $\delta$.

If frictions are present, the surplus available from assembly may not be arbitrated away. For instance, holdouts may ask excessive prices for their parcels and thereby make projects infeasible for the developer (Eckart, 1985; Strange, 1995). Similarly, individual landowners may attempt to increase their share of the surplus by being the final sale into an assembly. Such strategic delay may cause assemblies to fail (Menezes and Pitchford, 2004; Miceli and Segerson, 2007; Miceli and Sirmans, 2007). The public goods aspect of land assembly – the fact that assembly may increase the value of neighboring parcels not participating in the assembly – may also block arbitrage opportunities (Grossman and Hart, 1980; O’Flaherty, 1994). Finally, land use regulations may systematically block arbitrage opportunities. For example, regulation may bar a large building that would optimally occupy an assembled site. Returning to Figure 1b, if frictions block all assemblies, there will only be $q$ parcels of size $2a$ (the initial endowment) and the surplus to assembly, $s$, will persist. In the absence of

---

6 It is also possible that the market reaches a corner solution such that all parcels have been assembled. As this is not relevant empirically, we do not further consider this case.

7 In Eckart (1985) and Strange (1995), holdouts arise primarily due to two factors. First, land owners may have imperfect information on the value of the completed assembly and may therefore demand prices in excess of the value of the completed project. Second, assembly is characterized by indivisibility. A developer must assemble contiguous parcels and therefore cannot simply purchase an alternative parcel if he encounters a holdout.
spillovers, the shaded region is the deadweight loss associated with the frictions.\footnote{We only consider the effect of frictions on the \textit{quantity} of assembled parcels. Frictions may also cause the final land area assembled to be smaller than it would otherwise be. Munch (1976) and McDonald (2007) model this possibility.}

\section*{1.2 Testing for Frictions}

We now lay out a strategy to assess whether or not land assembly is inhibited by frictions.\footnote{The extremely limited empirical evidence on land assembly does not directly addresses the central question of how successfully the land market produces assemblies. Cunningham (2010) and Fu and Somerville (2002) document that the final seller in a land assembly receives a premium. Harding et al. (2003) provide evidence of more general deviations from the competitive equilibrium in the market for housing. A distinct literature explores whether the price per square foot of land increases in the size of the plot and is indirectly related to assembly (Coulson, 1989; Colwell and Munneke, 1999, 1997; Colwell and Sirmans, 1993; Brownstone and DeVany, 1991).}

Our test estimates the magnitude of the surplus $s$ accruing to successful assemblies in order to obtain a rough sense of the magnitude of the assembly market frictions. A large estimate of $s$ is consistent with substantial frictions in the market for assembly. This approach is similar in spirit to the work of Glaeser et al. (2005) and Glaeser and Gyourko (2002) on the regulatory tax. Glaeser et. al. reason that in the absence of regulation the extensive value of land – the per-unit value of land with a house on it – will equal the intensive value of land – the value of a marginal increase in the area of a lot. If the extensive value exceeds the intensive value, landowners should optimally choose to subdivide their land and sell a portion of it. Our approach applies what is, in essence, the reverse of this logic: in the absence of market imperfections, if land is worth more combined than divided, owners will choose to combine it.

Inferring the existence of frictions from the presence of surplus requires two assumptions. The first assumption is free entry into the market for development (or assembly). Developers earn zero profits; therefore the owners of the initial parcels size $a$ capture any surplus $s$ available from assembly. The value of an assembled parcel is $V(2a) + K$, where $K$ is the amount of capital placed on the newly assembled parcel. If the developer earns zero profits,
this post-assembly value must equal his costs. The developer’s costs are capital, $K$, assembly costs, $\delta$, and the purchase price of the unassembled land, $p_u$. Thus, $V(2a) + K = K + \delta + p_u$ which yields $p_u = V(2a) - \delta$. We can therefore estimate surplus as the difference between the sales price of to-be-assembled parcels, $V(2a) - \delta$, and the sales price of not assembled parcels, $2V(a)$: $V(2a) - \delta - 2V(a)$.¹⁰

The second assumption required to infer the existence of frictions from the presence of surplus is that the frictions in the urban land market operate purely as a supply constraint on assembly. This occurs if regulation prohibits assembly or if landowners cause assemblies to fail by asking prices that drive developer profits below zero. These supply restraints prevent arbitrage from entirely eliminating the surplus to assembly.

If the free entry and supply constraint assumptions fail to hold we will likely underestimate frictions in the market for assembly for at least two reasons. First, if there are barriers to entering the market for development, developers may capture a portion of the assembly surplus. The portion of the surplus accruing to the developer is reflected in the post-assembly sales price of the newly assembled parcel, not in the pre-assembly price we use to infer surplus. As a result, our estimate of surplus would be biased downward. Second, although the frictions described above almost certainly act as supply constraints on assembly, there may be other types of frictions. For instance, frictions such as regulatory costs (e.g., the time spent getting approval for a project) and strategic delay may increase the developer’s costs. Such an increase will reduce our measured value of surplus by depressing the amount a developer is willing to pay for assembled land. A given assembly may have no measurable surplus under our methodology, but large surplus in the absence of the friction-induced increase in developer costs. Thus, even a finding of no price premium for to-be-assembled parcels does not rule out the possibility that frictions influence the market for assembly.

We now discuss four potential objections to our test. First, a strict claim of inefficiency

---

¹⁰We deliberately remain agnostic on how sellers of input parcels split the surplus from assembly.
requires that surplus exceeds zero for the marginal assembly, while our empirical procedure recovers the average surplus to assembly. In our simple framework this is not a concern because there is no heterogeneity and the average and marginal surplus equate. In reality, though, there may be heterogeneity in the costs of assembly (keeping in mind that “good-institution” transactions costs are not driven by market frictions). With heterogeneous assembly costs, average surplus can exceed zero even if the surplus to the marginal parcel is zero.\footnote{Assume that there are contiguous pairs of parcels with unique assembly costs, \( \delta_i \), that there are no frictions in the land market, and that the market is in equilibrium (and hence no assembly takes place because all positive surplus assemblies have already occurred). Then a shock increases \( V(2a) \). Order the surplus of each pair, \( s_i = V(2a) - \delta_i - 2V(a) \), so that \( s_1 > s_2 > s_3 \ldots \). Unless all parcels assemble, there must be an \( s^* \) such that \( s^*_{i-1} > s^*_i = 0 > s^*_{i+1} \). The index \( i^* \) implicitly defines the number of assemblies produced by the shock. The marginal parcel \( i^* \) earns zero surplus, and all inframarginal parcels earn a surplus. We thank Robert Helsley for helpful discussion on this point.}

This type of heterogeneity in assembly costs, however, is unlikely to explain our findings for two reasons. First, we find that average surplus equals 40 percent of the market value of a parcel in its unassembled state. Assembly costs – demolition, land grading, “good-institution” transaction costs, etc. – are negligible relative to the value of some of the most expensive urban real estate in the U.S.\footnote{Rosenthal and Helsley (1994) document that demolition costs are only around \( 1\frac{1}{2} \) percent of the value of the underlying land for single family homes in Vancouver (which, like LA, has relatively expensive land).} For heterogeneous assembly costs to explain our estimates, such assembly costs would have to be extremely large relative to the value of the land in its unassembled state. Second, the distribution of assembly costs would have to be extremely disperse to generate an average surplus of 40 percent and a marginal surplus of zero.

Similarly, there may be variation across locations in the difference between the value of a parcel in its assembled state, \( V(2a) \), and its unassembled state, \( V(a) \), and hence in the surplus to assembly. However, in the absence of frictions, arbitrage should drive the assembly surplus to zero in all locations regardless of the initial surplus available. Were the outputs of assembly projects unique local properties, this might not be the case: Imagine a developer...
who assembles land to build a supermarket in an area that can support only one such store. However, our data show that over three-quarters of land assembled and developed is used for residential purposes. Such residential development is not the unique output that might give rise to this concern.

The second potential objection to our test is that it may take time for the market to complete enough assemblies to drive surplus to zero. During such a transition, surplus would be positive, even in the absence of frictions. However, the market for construction is quite deep in Los Angeles County. Many developers participate\textsuperscript{13} and even large construction projects can typically be completed quickly. The Census Bureau reports that a small multi-family building worth less than $3 million is completed in less than a year on average. Even very large buildings valued over $10 million with over 100 units usually take less than two years to complete.\textsuperscript{14} Thus, any transition period should be relatively short and is unlikely to explain a 40 percent surplus to assembly. While assemblies often take a significant amount of time to complete, the delay is typically caused by the very frictions, such as holdouts, whose impact we are attempting to quantify, not by the normal adjustment process of a well functioning land market.

The third possible objection to our surplus test is that many plots are constrained from assembly. For instance, physical barriers such as steep slopes may prevent assembly. Public capital, such as roads, may separate parcels and prevent assembly. A parcel ready for redevelopment may be next to a parcel with new or valuable capital, making redevelopment as part of an assembly economically infeasible. These factors are reasonably viewed as materially different from factors such as zoning and holdouts which may also prevent assembly. It would be unreasonable to label the failure to assemble two parcels separated by a road a market “friction.” However, arbitrage opportunities should cause the price of assembled

\textsuperscript{13}For example, the commercial developers association in Los Angeles has over 1000 members.
\textsuperscript{14}http://www.census.gov/const/C30/length.html
and unassembled teardown parcels to converge – and surplus to go to zero – unless there is a corner solution where no feasible assemblies exist. At least in Los Angeles, it seems clear that ample assembly opportunities remain and that a corner solution has not been reached (Landis and Hood, 2005).

The fourth potential objection to our test is that potential sellers into an assembly may have reservation prices higher than the market price for idiosyncratic reasons. For example, retirees may prefer to remain in their long-term place of residence or parents may wish that their children continue to attend a particular school. The need to buy contiguous parcels may force a developer to transact with such owners. (In contrast, in most market settings a buyer would choose to transact with a seller whose reservation price is less than or equal to the market price.) Thus, high reservation prices may cause properties selling into an assembly to transact at above market prices even in the absence of market frictions (Miceli et al., 2008).\textsuperscript{15}

We believe that reservation prices are unlikely to explain our surplus estimates for two reasons. First, while individuals with elevated reservation prices undoubtedly exist, the surplus to assembly should be arbitraged away as long as there are some potential assemblies where the owners have reservation prices equal to market prices (i.e. as long as there are enough such potential assemblies that surplus is driven to zero before developers must begin transacting with high reservation price sellers). Second, our empirical work devotes considerable effort to determining the extent to which our surplus estimates reflect high reservation prices. We use a number of different approaches, all of which suggest our surplus estimates primarily reflect market frictions, not high reservation prices. Most notably, although owners of commercial property are likely less prone to having idiosyncratically high

\textsuperscript{15}To illustrate, assume that the developer can always buy the first parcel of an assembly at market price and that the reservation price of the owner of the second parcel, $R(a)$, exceeds the market price: $R(a) > V(a)$. The true surplus from assembly becomes $s = V(2a) - \delta - 2V(a) - (R(a) - V(a))$. Reservation prices are unobservable and the measured surplus remains $s = V(2a) - \delta - 2V(a)$. The surplus estimate is therefore biased upward by the amount by which the reservation price exceeds the market price: $R(a) - V(a)$. 

12
reservation prices (Ellickson, 1973), these properties display the same surplus to assembly as do residential properties.

### 1.3 Sources of Land Assembly Frictions

Given that we find evidence for a non-zero surplus, we propose two tests to examine the source of frictions in the market for land assembly. For the first of these tests, assume that at time \( t \) parcels of size \( \frac{a}{2} \) and \( a \) exist. Assembly technology allows for generating parcels of size \( 2a \) through any combination of parcels yielding an area of \( 2a \). The convexity of the land value function suggests that \( V(a) > 2V\left(\frac{a}{2}\right) \). The assembly surplus is therefore higher for assemblies involving only parcels of size \( \frac{a}{2} \) because these smaller parcels have a lower opportunity cost than the larger parcels. As a result, in a market free of frictions, small parcels should be more likely to be assembled than larger parcels.\(^\text{16}\)

However, theorists argue that small parcels may increase the likelihood of private market frictions. Owners of small parcels may be more likely to ask excessive prices because, as a lower share of the ultimate assembly, their asking price is less likely to scuttle the project (Eckart, 1985; Strange, 1995). Similarly, the greater number of parcel owners involved in an assembly, the greater the odds of strategic delay (Miceli and Sirmans, 2007). Both these factors may cause assemblies with positive surplus to fail.

Given this, our first test for the sources of surplus examines the influence that parcel size has on the probability of assembly. A finding that larger parcels are more likely to be assembled suggests that private market frictions inhibit assembly.

Our second test for the sources of surplus examines the relative sales prices of to-be-

\(^\text{16}\)Assembly costs, \( \delta \), may be a function of the number of parcels included in an assembly (e.g. real estate transaction fees would be expected to be a function of the number of parcels). In such a case, we are implicitly assuming that as the number of input parcels increases, holding the size of the end assembly fixed, the opportunity cost of the input parcels falls more than the increase in assembly costs (roughly \( \frac{\partial \delta(n)}{\partial n} < -\frac{\partial V(n)}{\partial n} \)). This is a reasonable assumption given that assembly costs are small relative to the value of land.
assembled parcels by size. Evidence that small parcels command a significant per-square foot price premium over large ones (despite a lower opportunity cost of selling into assembly) would support the theoretical predictions that small parcels owners are unusually likely to ask excessive prices and engage in strategic delay. These two additional tests shed light on the source of the frictions, as both focus on frictions likely caused by private market failures.

2 Empirical Approach: Establishing the Existence of Surplus

In this section, we outline how we take the surplus test to the data. In the results section, we discuss robustness checks, including repeat sales methods, a falsification check, and a consideration of the role of reservation prices.

To estimate surplus, \( s \), we must recover the land value of both assembled and unassembled parcels. We recover the land value of an unassembled parcel using the technique pioneered by Rosenthal and Helsley (1994) and refined by Dye and McMillen (2007). This technique recovers the value of land using the sales of structures to be torn down. The value of such a teardown sale reflects only the value of the underlying land, since the capital is discarded.

We apply a similar logic to value the land used in assemblies. Most assemblies discard the existing capital and place new capital on the assembled site to take advantage of the larger building area. Intuitively, if the capital on the initial parcels were retained, there would be no gain from assembly. As a result, we assume that to-be-assembled parcels are teardowns and also use their sales price as a measure of the value of the land.\(^{17}\) We then estimate surplus as the difference between the value of assembly sales and the value of teardown sales.

\(^{17}\)As demonstrated below, however, our results are robust to limiting the assembly sample to cases where we can observe that the pre-assembly capital is torn down.
We estimate this difference with the following specification

\[
\log\left(\frac{\text{real sale price}}{\text{lot square footage}}\right)_{i,g,t} = \alpha_0 + \alpha_1 \text{assembly}_i + \text{year-quarter}_t + \text{neighborhood}_g + \alpha_2 X_{i,t} + \alpha_3 \text{amenities}_i + \varepsilon_{i,g,t},
\]

where \(\frac{\text{real sale price}}{\text{lot square footage}}_{i,g,t}\) is the per-square foot price of land for parcel \(i\) in neighborhood \(g\) at time \(t\) and \(\text{assembly}_i\) equals one for an assembly and zero for a teardown.

The estimation sample includes only teardown and assembly sales. Specifically, we select the sales sample in the following way. Each assembly has a start and end year (which may be the same, but frequently are not). We identify all parcels which are "input" parcels to assembly. We then identify the sales of these parcels that are no more than three years before the beginning of the assembly, no more than three years after the beginning of the assembly, and before the end of the assembly. Of these, we keep only the final sale. We use this window to keep only sales "close" to the time of assembly, which should be sales that reflect the value of land. For teardown sales, we keep only sales that are three or fewer years before the structure is torn down.

With this sample, \(\alpha_1\) captures the surplus to assembly relative to redevelopment within the existing parcel boundaries measured by teardowns. If \(\alpha_1 = 0\), there is no surplus to assembly, consistent with an absence of market frictions.

Interpreting \(\alpha_1\) as the surplus to assembly requires that assemblies and teardowns are comparable in the unobserved determinants of price, \(\varepsilon_{i,g,t}\). Assembly, however, may be correlated with unobservable determinants of price for at least two reasons. First, rising land values often dictate increasing the capital-to-land ratio and may motivate assembly. Thus, land with a particularly high value may be more likely to assemble than less valuable land (i.e. there may be a reverse causality problem). Second, some of the very frictions we are attempting to quantify, such as zoning, may make high value land less likely to assemble.
For instance, more stringent zoning in Malibu may make assembly less likely there than in Watts. Because land is more valuable in Malibu than in Watts for reasons having nothing to do with the likelihood of assembly, this may introduce bias.

We tackle the above endogeneity concerns by observing that the value of land, virtually by definition, is a function of location. We therefore include a very fine set of geographic fixed effects, either census tract indicators or census block group indicators, \( \text{neighborhood}_g \). The comparison of land price between assemblies and teardowns therefore comes only within very small areas. There are 2,054 census tracts and 6,346 block groups in Los Angeles County. The median tract contains 985 parcels, and the median block group 290.\(^{18}\)

Of course, some elements of location vary even within small geographic areas. For instance, access to a highway may differ within a neighborhood. We therefore control for distance to the nearest major highway, nearest major road, and the shortest distance to urban and commuter rail with the \( \text{amenities}_i \) vector. To control for the market-wide evolution in price over time we include a full set of indicators for each quarter in our sample, \( \text{year-quarter}_t \) (i.e., indicators for 1999Q1, 1999Q2, etc, are included) and we allow the coefficients on these indicators to vary by the residential or non-residential status of the input parcel.\(^{19}\) To control for parcel attributes, we include a vector of parcel characteristics, \( X_{i,t} \), which includes a cubic in lot size and and indicators for the pre-assembly or pre-teardown use of the parcel (i.e. single family, condo, non-residential, etc.). Finally, we report standard errors clustered at the city level.\(^{20}\)

\(^{18}\)Our test relies on the co-existence, in geographically comparable areas, of both teardown and assembly parcels. Appendix Figure 1 shows census tracts in Los Angeles County, and marks areas that ever (1999 to 2010) have both at least one assembly and one teardown; areas that ever have only teardowns; areas that have only assemblies; and areas that have neither. Roughly three-quarters of all tracts have an assembly over the period of study; this figure is 80 percent for tracts with teardowns. Roughly 65 percent of all tracts have at least one assembly and at least one teardown over the period of study. The map shows that these redeveloped areas are located widely across the county.\(^{19}\)Pooling different property types together in equation (2) is appropriate because we are valuing land, not structures. Furthermore, it is quite common for the input parcel use to differ from the assembled parcel use (e.g., commercial properties are assembled and a condo building placed on the new parcel).\(^{20}\)Our approach departs from the teardown literature in one important regard. The teardown literature
3 Land Assembly Definition and Institutions

This section presents our empirical definition of land assembly and discusses the institutions for assembly in Los Angeles County.

To define land assembly, we first define a “parcel change group.” A parcel is part of a parcel change group if it or its ancestor or descendant parcel(s) ever changes. However, parcels combine and disaggregate in a number of different ways, so membership in a parcel group does not alone indicate assembly. The list below presents three examples of possible parcel changes.

A. $3 \rightarrow 1 \rightarrow 7$
B. $1 \rightarrow 5$
C. $8 \rightarrow 1 \rightarrow 2$

We define a change group to have land assembly if any part of the parcel change group goes from $n > 1$ properties to one. In the example above, this includes cases A and C, but excludes case B. Case A is an instance of net disassembly (3 parcels into 7 parcels), though it contains assembly as an intermediate step (3 parcels into 1 parcel). We define case A as a land assembly because in most such instances redevelopment cannot occur without the assembly step. For instance, a developer may wish to convert multiple detached single family controls for selection into redevelopment using a Heckman two-stage procedure. Accordingly, coefficient estimates yield marginal effects for the untruncated, latent dependent variable. When the goal is to recover the value of all land, whether redeveloped or not, this is an appropriate approach. Because our aim differs, we estimate equation (2) using OLS. Two points bear emphasis. First, the OLS coefficients recover marginal effects for the truncated, observed dependent variable. These effects are precisely those required for the primary test. Specifically, the OLS estimate of $\alpha_1$ answers the question: among redeveloped parcels (i.e., in the observed portion of the distribution), is there excess value to assembly? The arbitrage argument underlying the test is only valid for parcels actually undergoing redevelopment. Arbitrage should not eliminate the surplus to assembly for parcels whose condition makes redevelopment suboptimal (e.g., those containing capital too valuable for redevelopment). Second, although the conditional expectation function is non-linear, OLS provides a well-defined minimum mean squared error linear approximation. Angrist and Pischke (2009, page 102-3) and Cameron and Travedi (2005, page 542) discuss using OLS to fit the conditional expectation function of a left-truncated distribution.
home parcels into denser townhouse style homes. The lots first need to be combined before they can be properly subdivided into the smaller townhouse lots.\textsuperscript{21}

When is the type of land assembly we have defined required? Regulations for land assembly are the province of cities, or the county for unincorporated areas. In general, cities do not require developers to assemble parcels, even when a new structure spans more than one parcel. However, there are two circumstances under which formal assembly is required.\textsuperscript{22}

The first is when the new land use will be condominiums. Each unit in a condominium must have a separate parcel, as each unit may have a unique legal owner. Therefore, any land combined for condos must be assembled. The second exception from the laissez-faire policy is a function of the use of the property. Suppose that a city’s zoning requires two parking spaces for each multi-family unit, and that the developer has purchased two parcels upon which to build a new multi-family development. If the developer builds the parking on one parcel and the structure on the other, he is required to legally assemble the parcels. Cities make such a requirement to ensure that all future sales keep parcels in compliance with zoning regulations.

Outside of these two exceptions, a developer may purchase adjoining land with the intent of building new structures but not go through the formal process of legal assembly.\textsuperscript{23} It is the legal assembly which we observe in the data. For the purposes of our estimation, this type of underreporting likely biases our estimates of the prevalence of frictions downward, by mistakenly putting some assembled parcels in the teardown comparison group.

While there are substantial benefits to legal assembly, the costs in terms of administrative

\textsuperscript{21}Though this definition of land assembly could include parcels assembled via eminent domain, our empirical analysis of prices uses only arm’s length sales. Furthermore, the municipal officials with whom we spoke suggested that eminent domain is used very sparingly.

\textsuperscript{22}Information in this section comes primarily from an interview with Wolfgang Krause, Chief Planner, City of Glendale, May 2010. To the best of our knowledge, these two circumstances do not vary across regulatory jurisdictions in the county.

\textsuperscript{23}In such cases, with multiple owners, owners usually write legally binding easement agreements across properties.
burden and fees are extremely low. Once an owner acquires adjacent parcels, if he wishes to legally combine them, he need only fill out a form from the County Assessor’s office. There is no charge. Importantly, the legal land assembly process does not trigger a reassessment under California’s Proposition 13. Proposition 13 limits the increase in a property’s assessed value to two percent per year, with the assessed value resetting to the market value at sale. A developer may face an increased assessment due to property purchase, but not due to the legal act of assembly.\textsuperscript{24} Thus, legal assembly is virtually costless. Turning to the benefits of assembly, interviews with practitioners suggest that legal assembly is very likely for projects requiring financing, since assembly lessens the financier’s cost in the case of default (interview citations appear after the bibliography). In addition, selling an assembled parcel, rather than multiple unassembled parcels, reduces paperwork and uncertainty in future transactions. Thus, our interviews suggests that the combination of substantial benefits and low costs results in developers choosing legal assembly over informal assembly in most cases.

To give a sense of the prevalence of assembly, Figure 2 presents the total number of assemblies in Los Angeles County divided by the total number of permits issued for residential construction by year from 1999 to 2008. We expect that this number actually underestimates the importance of land assembly. While one permit allows for construction of one unit, one assembly may (and frequently does) result in more than one unit. For instance, three parcels of land may be assembled to construct a multi-story 30-unit condo building. Thus, while three parcels are assembled, permits are given for 30 units. It is also possible that this number overstates the impact of assembly, since permits include only residential construction and our data include all land for assembly. However, the majority of assembly land (like all land) is used for residential purposes. Even given this likelihood of underestimation, assemblies account for roughly 7 to 20 percent of residential permits per year from 1999 to 2009 and account for a substantially larger share in 2010 and 2011.

\textsuperscript{24}This information comes from the Special Investigations Section, Los Angeles County Assessor.
4 Data

Our project relies on multiple sources of data. We summarize the data here, and refer interested readers to our lengthy Data Appendix for full details on all data inputs and data construction details. The three key components of our data are the annual property-level data for Los Angeles County, sales data for properties, and census neighborhood measures.

Our annual property data consist of three key parts: (i) twelve annual cross-sectional observations of the 2.3 million parcels in the County of Los Angeles, (ii) an administrative dataset from the County Assessor listing all parcels that change, and the identification numbers of the parcel(s) to which they change, and (iii) electronic maps with geographic information on all properties.

The annual cross-sections are the heart of the dataset. In each year from 1999 to 2011 (except for 2003, which we have been unable to obtain) we observe attributes about each individual piece of property in the 88 cities and the large unincorporated area of Los Angeles County. We observe too many attributes to list here, but briefly the data include attributes about the property itself (e.g., size and location); attributes about the building on the property (e.g., building size); and attributes about the legal regime that governs the property (i.e., the use and zoning rules for each property). Thus, this part of the dataset includes somewhat more than 24 million observations with many descriptive variables.

The second part of the data is a file that allows us to take the 12 cross-sections and make them into a true panel by linking property identification numbers over time. Though most properties retain a constant identification number throughout the sample, some properties split or merge. Our dataset of all property identification number changes allows us to follow each initial piece of land to its current, perhaps aggregated or disaggregated, form. While this task is conceptually simple, in practice it has been exceedingly difficult, and the bulk of our data assembly has been devoted to making sure that we have built these linkages
The third and final part of the annual property data is electronic maps of all parcels. These maps, which we have from 2006 onward, allow us to pinpoint the exact location of each individual property and calculate distances from one property to another, or from a given property to key urban amenities, such as light rail stops or freeways. These maps also allow us to assign each property to a unique census block group.

We combine this panel of all properties in the county with all property transactions by property identifier. Specifically, we observe the last three sales on each property as of 2006, and sales in the last two years each year from 2009 to 2011. This leaves a small gap of sales in 2006. We limit the sample of transactions to include only arms’ length transactions and make other small adjustments as described in the Data Appendix.

We measure neighborhood economic and demographic factors with data from the 1990 and 2000 Decennial Censuses at the block group level. To use the 1990 block group data, we use GIS mapping to make a correspondence from 1990 to 2000 census block groups.

Finally, we define a property as a teardown if the structure’s age changes in our panel. Specifically, we require that the replacement structure be newer than the old structure, that the new structure is built after 1998, and that the old structure was built before 1990.25

5 Results

This section presents results from our test for the existence of surplus. It also contains robustness checks which aim to demonstrate that the estimated surplus reflects neither the endogeneity of assembly location nor high reservation prices.

---

25We observe structure age at only a single point in time each year (in July). We therefore omit teardown sales in year \( t \) when the new structure appears in year \( t \) because we cannot determine if the structure was built before or after the sale.
5.1 Existence of Surplus

We motivate our comparison of assembly to teardown parcels by presenting their mean characteristics in columns (1) and (2) of Table 1. As a reminder, the sample contains only sales of assembly and teardown parcels that occur shortly before assembly or teardown. In order to provide context, column (5) displays the statistics for non-assembly and non-teardown parcels. Overall, assemblies (column (1)) and teardowns (column (2)) are located in similar types of neighborhoods. Although there are statistically significant differences between the groups – column (3) – the magnitude of the differences are economically small (e.g., a black neighborhood share of 5.3 percent for assemblies versus 6.0 percent for teardowns). Moreover, regression-adjusted mean differences that condition out census tract fixed effects, presented in column (4), generally show extremely small and imprecise differences. This similarity is advantageous for our primary test given its requirement that assemblies and teardowns be comparable in terms of the unobserved determinants of price.

A glaring exception to the comparability is the use category of the parcels before the assembly or teardown occurs: teardown parcels are much more likely to be single family than are assembly parcels. We take great care below to address this difference. All specifications include a control for use type and we allow the coefficients on the year by quarter of sale controls to differ by residential and non-residential status. We also present specifications which restrict the sample to only single family parcels or only non-residential parcels to make teardowns and assemblies as comparable as possible.

Table 2 presents the results for our test of surplus – absent frictions, the price of teardowns and assembly parcels should equate – implemented by estimating equation (2) on the sample of teardown and assembly sales. The coefficient estimate in column (1) indicates that being sold into an assembly is associated with a roughly 40 percent price premium relative to being

\[ \text{26 Demographic characteristics, such as the poverty rate, are from the census and are measured at the block group level.} \]
sold for redevelopment without a change in parcel boundary. The extremely large magnitude of the assembly surplus suggests substantial frictions in the market for assembly.

Columns (2) through (5) present alternative specifications. Column (2) addresses within neighborhood variation by adding neighborhood demographic controls at the block group level and controls for local amenities. Column (3) further addresses intra-neighborhood variation by replacing the tract fixed effects with very finely grained block group fixed effects. Column (4) controls for the evolution in price specific to each tract by including tract-year terms. Relative to the sample size of about 11,000 parcels, this is an extremely saturated model. It is also very demanding: identification of the assembly premium comes solely from comparing assemblies to teardowns within census tracts in the same year. Regardless of specification, the magnitude of the surplus estimate varies little, ranging from around 35 to 40 percent.

It is possible that assemblies occur with the aim of future, rather than immediate, redevelopment. If so, the sales price of the to-be-assembled parcels may reflect the expected return to any existing capital over the period before redevelopment (McMillen and O'Sullivan, 2011). Such a scenario would bias our surplus estimates upward. To address this possibility, in column (5) we restrict our sample to only assemblies where the existing capital is immediately torn down. (Due to the structure of our data, we under-identify these parcels. See Section 3 of the Data Appendix for details.) The magnitude of the surplus estimate is virtually the same as the unrestricted sample.

To address the concern that assembled parcels are systematically less likely to be single family than are teardowns, columns (6) and (7) restrict the sample to single family parcels. The restriction makes the teardown and assembly samples comparable in terms of pre-assembly use. The surplus estimates remain similar to those produced by the full sample.

These surplus results are credible only insofar as we have controlled for the endogenous location of assembly, and shown that the results are not driven by owners’ high subjective
valuation of their homes. We deal with each of these issues in turn, starting with a falsification exercise and a repeat sales analysis that address the issue of endogenous location.

We estimate the falsification check with

\[
\log\left( \frac{\text{real sale price}}{\text{lot square footage}} \right)_{i,g,t} = \lambda_0 + \lambda_1 \{\text{pre-assembly very close neighbor}\}_{i,t} + \text{year-quarter}_t + \text{neighborhood}_y + \lambda_2 X_{i,t} + \lambda_3 K_{i,t} + \epsilon_{i,g,t},
\]

where \( K_{i,t} \) is a vector measuring the value of capital on parcel \( i \) at time \( t \) and \( \{\text{pre-assembly very close neighbor}\}_i \) is an indicator variable equaling one if parcel \( i \) is a very close neighbor of an assembled parcel and \( t \) is one to three years prior to the start of the assembly.\(^{27}\)

The very close neighbors of assembled parcels are not themselves assembled and, if our estimation strategy is valid, should not receive an assembly premium. On the other hand, if the estimated premium to assembly reflects bias from very localized unobserved amenities—those whose effect on property values is more geographically limited than a block group—we would reasonably expect these amenities to be reflected in the price of the assembled parcels’ very close neighbors. Thus, a positive and precise \( \lambda_1 \) indicates that the Table 2 results may be biased. In order to preserve the assembly-teardown comparison, we limit the sample to the very close neighbors of teardowns and assemblies three years before assembly or teardown. \( \lambda_1 \) therefore captures the “surplus” to being a very close assembly neighbor relative to being a very close teardown neighbor.

We define very close neighbors as parcels located on the same “map book page” as assembled parcels. Map book pages are geographical units defined by the County Assessor’s office. They are quite small, containing an average of only 26 parcels, and typically encompass a single square block. Figure 3 displays a representative example.

\(^{27}\)We focus on the years just before the assembly because the assembly may directly influence the value of neighboring parcels. Such spillovers would contaminate the falsification check.
Table 3 presents the results. Column (1) suggests that very close assembly neighbors sell at a slight discount relative to very close teardown neighbors, although the estimate is only marginally precise (at the 10 percent level). Unlike teardowns and assemblies, the market value of neighboring parcels likely includes the value of capital. Column (2) therefore controls, in a very flexible manner, for the parcel’s capital. The discount falls a bit and is imprecise. Using block group fixed-effects produces a diminishingly small point estimate—column (3). Including tract-year fixed effect in column (4) produces a small and marginally significant negative effect. Restricting the sample to single family parcels produces an extremely small, imprecise estimate—column (5).

Overall, these results suggest that there is little bias involved in comparing assemblies to teardowns and they strongly suggest that there is no upward bias in the comparison: The upper 95th percent confidence interval for the estimate in column (3) is a mere 0.028 and the analogous values are smaller for the remaining columns.

In order to further address the endogenous location of assembly, we now turn to a repeat sales approach, which we estimate using the following specification

\[
\log\left(\frac{\text{real sale price}}{\text{lot square footage}}\right)_{i,t} = \beta_0 + \beta_1 \{\text{redevelop}\} \ast 1\{\text{ever assembly}\}_{i,t} + \beta_2 1\{\text{redevelop}\} \\
+ \beta_4 K_{i,t} + \beta_5 K_{i,t} \ast 1\{\text{redevelop}\} + parcel_i + \text{year-quarter}_t \\
+ \varepsilon_{i,t}.
\] (4)

We restrict the sample to teardown and assembly parcels which have, in addition to the teardown or assembly sale, a previously occurring sale (after 1985). The indicator 1\{redevelop\} the presence of capital in a relatively non-parametric manner by including the full set of interaction terms between indicator variables for the decile of the vintage of the existing capital (year built) and indicator variables for the decile of the quantity of the capital (square feet of structure per square foot of land). This approach fails to account for both differences in depreciation across properties and differences in the initial quality of the capital. We therefore also control for the capital to land ratio (assessed improvements/assessed land value), and the value of capital per square foot of land (assessed improvements/lot size). We allow all of the coefficients on the capital variables to vary by residential and non-residential pre-assembly use.
equals one when the observation is the sale immediately before either an assembly or teardown. The indicator \(1\{\text{ever assembly}\}\) is one if the parcel is ever sold into an assembly in our sample; it is not included as an uninteracted, main effect because it is collinear with the parcel fixed effect. Thus, \(1\{\text{redevelop}\} \times 1\{\text{ever assembly}\}\) equals one if this sale is the final sale before assembly, and \(\beta_1\) is the coefficient of interest.

This repeat sales estimation can be viewed as a double difference: relative to the same parcel over time, and relative to teardowns, is there a premium for being the last sale before an assembly? The principle advantage of the approach is that the parcel fixed effect, \(\text{parcel}_i\), controls for any time-invariant feature of the parcel such as greenery, freeway access, proximity to commercial strips, etc.

While the “redevelopment” sales values should not reflect the value of capital, the earlier sales values likely will (i.e., the earlier sale buyers likely intended to use the capital located on the parcels). We therefore include controls in equation (4) for capital, \(K_{i,t}\), and capital on the final sale \((K_{i,t} \times 1\{\text{redevelop}\})\).

Table 4 presents the repeat sales results. From the smaller numbers in the observation rows, it is clear that the data requirements of the approach yield a substantially thinner sample than that used for the initial test in Table 2. This is particularly true for the number of unique assemblies and teardowns. The repeat sales approach thus places significant demands upon the data. Column (1) presents a specification which lacks the capital controls and column (2) adds in these controls. Both specifications yield an assembly surplus of about 15 percent. Unlike the initial test, these estimates are sensitive to controlling for the geographic-specific evolution in prices. Controlling for city-year effects in column (3) boosts the surplus estimate to 20 percent.\(^{30}\) While smaller than the surplus estimate produced by our principal

\(^{29}\)Given the much smaller sample size, the set of capital controls used for the repeat sales analysis is more parsimonious than that used for the falsification check on Table 3. See the note on Table 4 for a complete list of the capital control variables.

\(^{30}\)The tract-year terms used elsewhere in the paper cannot be employed here given the thinness of the estimation sample.
approach, 20 percent remains a sizable surplus to assembly.

We conclude our analysis of surplus by considering whether our estimates of surplus are driven by high subjective valuations. Subjective valuations should be particularly high for single family homes (Ellickson, 1973). Therefore, in order to assess the importance of reservation prices in determining surplus, we examine the difference in surplus between single family and non-single family parcels. Column (1) of Table 5 presents results from our surplus estimation (Table 2) using a sample that excludes single family homes. The surplus estimate of 33 percent is extremely similar to the analogous estimate of 36 percent for single family homes (column (7) of Table 1). Similarly, column (2) further restricts the sample to non-residential parcels which we expect would have lower subjective valuations, on average, than single family homes. The result is again quite similar to the estimate for single family homes. Finally, single family owner-occupants would likely have higher subjective valuations than absentee owners. In column (3) we restrict the sample to single family homes and allow the assembly premium to vary by owner status. If reservation prices were the primary factor driving the surplus estimate, owner-occupied homes should have a higher surplus. The results suggest the opposite, but are quite imprecise. In sum, the patterns of surplus by parcel use and ownership status are not consistent with surplus consisting primarily of high reservation prices.

5.2 Causes of Assembly Surplus

Broadly, we construe the results from Tables 2 through 5 as robust support for the existence of an economically significant premium to assembled land. Given this, we now turn to a consideration of the sources of this surplus. Surplus can be driven by both public and private market frictions. Public frictions that yield surplus are regulations on the use of land. Private market frictions include problems of holdouts and other bargaining issues. We use
two tests to assess whether private market failures contribute to the surplus.\footnote{A natural third test would examine the land assembly premium as a function of the time of sale, where later selling parcels would garner a larger premium. Unfortunately, the structure of our data precludes such an approach. Market participants told us that sales into assembly are frequently “contingent sales” so that no sale of any potentially assembled property occurs until the developer has gathered a sufficient amount of land. In such a case, all properties that sell into the assembly officially transact on the same date, even though the actual bargaining date may differ substantially. We observe only the official transaction date, which is frequently the same for parcels selling into a given assembly.} The results point toward an important role for private market failures in creating assembly surplus. We cannot rule out the possibility, though, that public market failures may also play an important role.

Starting with the first test: in a well functioning market, smaller parcels should be more likely to assemble than larger parcels due to the convexity of the land value function in areas undergoing land assembly. Alternatively, in a poorly functioning market, small parcels are particularly prone to market frictions such as holding out and strategic delay. We therefore examine the influence of parcel size on assembly probability. To do so, we use the cross-section of all 2 million county parcels from the first year of the sample (1999).\footnote{Summary statistics for this sample are in Appendix Table 1.}

The estimating equation is

\[
\text{assembly}_{i,g} = \gamma_0 + \gamma_1 \log(\text{lot square footage}_i) + \text{neighborhood}_g + \gamma_2 \text{amenities}_i + \gamma_3 K_{i,t} + \varepsilon_{i,g},
\]

where \(\text{assembly}_{i,g}\) equals one if the parcel is involved in an assembly over the following 12 years of the sample and zero otherwise, and \(\text{lot square footage}_i\) is the size of the parcel. \(\gamma_1\) captures the marginal effect of lot size on the probability of assembly and is the coefficient of interest.

The coefficient \(\gamma_1\) is properly identified when lot size is uncorrelated with unobserved determinants of assembly, \(\varepsilon_{i,g}\). There are at least three possible reasons to be concerned that this may not be the case. First, the likelihood of assembly may vary by location, and location
may be correlated with parcel size. For example, parcels near the urban center may be ripe for assembly and redevelopment due to traffic congestion. These parcels may be relatively small, but it is their lower commute time, not their size, driving the assembly decision. As before, we net out such neighborhood-specific factors with tract or block group fixed effects, so that all our comparisons are made within a given, limited geographic area.

The second threat to the credibility of the identifying assumption is the possibility that large plots tend to have more valuable capital per square foot of land than smaller parcels. All else equal, the more valuable the capital on a parcel, the less likely the capital will be scrapped to allow for redevelopment and the less likely is assembly. We therefore control for the presence of capital on each parcel in a very flexible manner (see the note to Table 6).

A third reason lot size may be correlated with the error term is because not all lots are “assemble-able,” and “assemble-ability” may be correlated with lot size. In general, larger parcels should be more likely to be unable to assemble because they have no contiguous neighbors. However, this possibility would bias our estimation toward small parcels being more likely to assemble, and hence make it less likely we will conclude that the market for assembly is inhibited by frictions.

Column (1) of Table 6 indicates that a 10 percent increase in the size of a parcel increases the probability of ever being assembled by 0.1 percent. This is a large effect, equal to around 10 percent of the sample mean probability of ever assembling (see the “Share Ever Assembled” row). The remaining columns use block group fixed effects—columns (2) and (4)—and include the capital controls—columns (3) and (4). These permutations have little effect on the lot size coefficient.\footnote{If we exclude the least dense quartile of parcels in terms of the population density of their block group from the sample, ensuring that our results are driven by outcomes in a dense urban setting, results are little changed.}

We believe that these results are unlikely to be driven exclusively by a correlation between reservation prices and lot size, or by land use regulations. Conditional on the right-hand
side controls, which include the pre-assembly use of the parcel, there is no obvious reason why reservation prices should vary by lot size. Similarly, land use regulations are not likely to create an incentive to use large parcels in an assembly.\textsuperscript{34} Thus, we interpret this evidence as suggesting that private market frictions are prevalent in the market for land assembly.

Our second test for the causes of assembly surplus relies on a similar logic to that of the previous test. In the absence of frictions, the convexity of the land value function requires that small parcels should not receive a premium relative to large parcels when they sell into an assembly. Alternatively, when market frictions are present, small parcels may command a premium. We implement this test with a panel specification.

\[
\log\left(\frac{\text{real sale price}}{\text{lot square footage}}\right)_{i,g,t} = \theta_0 + \theta_1 \log(\text{lot square footage}_i) + \text{year-quarter}_t + \text{assembly group}_g + \theta_2 \text{amenities}_i + \varepsilon_{i,g,t}, \quad (6)
\]

where \(\text{assembly group}_g\) is a fixed effect for each assembly group — a set of contiguous parcels that are assembled together. \(\theta_1\) captures the marginal effect of lot size on sales price and is the coefficient of interest. The sample is limited to assembly sales.

The \(\text{assembly group}_g\) term ensures the influence of lot size on sales price is measured solely \textit{within} groups of parcels assembled together. The identifying assumption required for equation (6) — that lot size is uncorrelated with the unobserved determinants of price — is therefore extremely plausible. To-be-assembled parcels are sold only for their land value. Within an assembly group parcels are contiguous and thus likely have very similar location value.

Table 7 presents the results. Column (1) shows that a 10 percent increase in parcel

\textsuperscript{34}In fact, land use regulation may provide an incentive to assemble small parcels. Consider minimum setback requirements. Under a fixed setback requirement, assembling parcels relaxes the regulatory constraint as the adjoining borders of the input parcels become interior to the assembled parcel and do not require a setback (Shoup, 2008). Hence, a higher percentage of the assembled land can have capital situated on it relative to the unassembled land. The gain along this dimension is greater for joining together several small parcels than it is for joining together a few large parcels.
size reduces the sales price of a to-be-assembled parcel by roughly 8 percent. Column (2) includes the distance to amenities controls, which vary somewhat within a parcel group, and produces nearly identical results. There is little reason to think that reservation prices vary with lot size within a parcel group, conditional on use. Thus, the substantial premium to small parcels supports the hypothesis that the owners of these parcels tend to hold out and demand higher than average prices for their land – behavior which works to reduce the number of successful assemblies. While it is possible that land use regulation differs within assembly groups in a manner correlated with lot size, we view this evidence as most consistent with private market failures.

5.3 Welfare Implications

Given that our evidence suggests a substantial deadweight loss associated with the inhibition of land assembly, it is natural to ask whether this inhibition causes an overall welfare loss. We explore this issue at length in an appendix and summarize our conclusion – that a welfare loss is likely but not certain – here. For more land assembly to decrease welfare, it must exert negative external effects that outweigh any decrease in direct deadweight loss (the shaded area in Figure 1b). We divide the external effects of land assembly into local and non-local (i.e. metropolitan area wide) effects. To estimate the local external effects of land assembly, we estimate a modified version of equation (3), where we replace $1\{\text{pre-assembly very close neighbor}\}$, with an indicator for being on the same map book page as an assembly after the assembly, and we restrict the sample to non-assembly and non-teardown sales. Intuitively, this specification estimates whether parcels very close to the assembly experience a price change after the assembly. In short, we observe no capitalization of assembly into nearby properties, suggesting no local externalities to land assembly.

Therefore, for additional land assembly to decrease welfare, metropolitan area externalities to assembly must be quite negative. We believe this is unlikely, but cannot rule out this
possibility. Furthermore, assessing the welfare consequences of frictions is inherently difficult in an urban setting. Most urban models assume market failures that generate agglomeration and congestion. In such a second-best setting, removing a negative externality, such as land assembly frictions, need not improve overall welfare (e.g. Helpman, 2007; Kanemoto, 2013). Overall, though, we believe the combination of direct evidence of deadweight loss and the absence of evidence for negative local spillovers points toward the possibility of a large welfare loss from land assembly frictions.

6 Conclusion

The results of this paper provide robust confirmation of the hypothesis that the market for land assembly is inhibited by frictions. We find that land selling into assembly garners a 40 percent premium. Because we find that smaller parcels are less likely to be assembled and fetch higher per square foot prices within a given assembly, we contend that at least part of the overall frictions we document are due to private market failures. Though the evidence is not conclusive, it is possible that the frictions inhibiting land assembly are associated with large and negative welfare effects.

While the problems we document are salient for the developed world, they are likely to be just as salient, if not more, for the developing world, where urban growth often confronts problems of assembly. Seshadri (2011) holds that problems in land assembly inhibit the growth of special economic zones in India, and media coverage of holdouts in Chinese land assembly is abundant (for examples, see French (2007) and Molly (2012)).

If the market for private land assembly operates as poorly as suggested by this work, it is natural to look to government for remediation. The most recent large-scale government action to assemble land is known as “urban renewal,” a process in the United States, Canada and in some parts of Europe in the 1960s and 70s. Urban renewal used the government’s
power of eminent domain to assemble small parcels of land, predominantly in the urban
core. Urban renewal, however, ended amid charges of developer cronyism and racism, has
largely been judged harshly by historians (Cord, 1974). While our findings suggest that the
land assembly portion of urban renewal would likely not have been achieved by the private
market, our results from the private market have little to offer in understanding the potential
value of government-driven assembly.

Alternatively, there may be a middle ground between the private exchange of land and
direct government intervention. Under the practice of “land readjustment,” redevelopment
districts are formed and land assembly occurs if a majority of land owners in the district vote
for it. The owners are given a stake in the new development as compensation. The practice
has been successfully used in a number of countries, including Germany, South Korea, and
Israel (Hong, 2007). Land readjustment may provide a mechanism for overcoming the private
market failures inherent in land assembly, while mitigating the costs associated with direct
government intervention. Another possible middle ground approach is graduated density
zoning, which awards the right to build at greater density to larger lots. The “density bonus”
increases the value of large lots and encourages assembly. Although it does not eliminate
holdouts, it may generate a fear of being left out and therefore reduce the prevalence of
holdouts (Shoup, 2008).

More broadly, our evidence argues that “tragedies of the anti-commons,” in which prob-
lems of fragmented ownership impede socially optimal outcomes, are of economically signif-
icant magnitude. While we illustrate these problems in the context of land assembly, they
apply in many contexts with fragmented ownership, such as spectrum rights or intellectual
property.

Figure 1: Theoretical Framework

(a) Land Value Function is Convex

Note: Figure 1a illustrates convexity in land prices. Were land prices to increase linearly, they would follow the dashed line ending at $2V(a)$. When prices are convex, as shown with the thick curve, $V(2a) > 2V(a)$. The thin curve shows how the convex curve flattens out as developers complete assemblies and the market moves toward equilibrium. In equilibrium, we expect the price of assembled and unassembled parcels to differ only by the “good institution” cost of assembly, $\delta$. 

(b) Surplus to Assembly, $s$
Sources: Permit data from Census Bureau, assemblies calculated from authors’ dataset. See Data Appendix for details.

Notes: While the Census Bureau counts one permit for each new unit, one assembly (in our terms) may result in more than one unit. This means that our measure in the chart may understate the importance of assembly. However, the Census Bureau counts residential permits only, while our measure of assemblies includes assemblies that result in non-residential construction. In this sense, our measure overstates the importance of assembly. Because we do not have a cross-section of properties from 2003, we attribute all assemblies in 2002 and 2003 to 2002; for the purposes of this chart, we split the assemblies in 2002 evenly between 2002 and 2003. Though our assembly information continues through 2011, this chart ends in 2010 when the permit data end.

Notes: The dependent variable is log(real sales price per square foot). We use the largest consistent sample of sales in the three years before teardown or assembly, where the teardown or assembly occurs between 1999 and 2011. Standard errors clustered at the city level are in parentheses. Significance levels are denoted by *** for significant at the 0.1% level, ** for significant at the 1% level, * for significant at the 5% level, and + for significant at the 10% level. Neighborhood demographics include the following variables in both 2000 level form and as changes between 1990 and 2000 levels: poverty rate, neighborhood share black, neighborhood share Hispanic, share of housing units vacant and share of housing units owner-occupied. Use classifications include indicator variables for single family, non-condo multi-family, condo, vacant and other. Distance to key amenities include measures for the shortest distance from each parcel to three amenities: a highway entrance or exit, a metrolink stop (commuter rail), and a metrorail stop (subway or light rail).

Notes: The dependent variable in these regressions is log(real sales price per square foot). 1*{Pre-Assembly Very Close Neighbor} equals one for parcels that share a mapbook page with a parcel that will assemble within three years. We use the largest consistent sample of sales in the three years before teardown or assembly, on mapbook pages where the teardown or assembly occurs between 1999 and 2011; however, we exclude all teardown and assembly sales. Standard errors clustered at the city level are given in parentheses. Significance levels are denoted by *** for significant at the 0.1% level, ** for significant at the 1% level, * for significant at the 5% level, and + for significant at the 10% level. Use classifications, amenities and demographics are as given in the note on Table 2. The capital controls include the value of improvements to the land per square feet, the ratio of the value of improvements to the land (i.e. capital to land ratio) and a full set of interactions of indicators for decile of structure age with indicators for decile of structure square feet divided by lot square feet (a measure of the quantity of capital). For both deciles an 11th indicator variable is added to denote missing values.
