Abstract

This paper develops an unobserved components model for U.S. real GDP that allows for both asymmetric transitory movements and correlation between the permanent and transitory innovations. The asymmetry is modeled using Markov-switching in the transitory component in the spirit of Kim and Nelson's (1999) version of Friedman's plucking model. The findings suggest that ignoring the correlation between permanent and transitory movements underestimates the role of permanent movements, whereas ignoring asymmetry in the transitory component underestimates the role of temporary movements in U.S. real GDP. These results imply that both permanent movements and asymmetric transitory shocks are important for explaining post-war output fluctuations in the U.S. and for explaining the recession that began in 2007 in particular.

I also thank Jahangir Hossain and Amr Moubarak for helpful research assistance. All remaining errors are my own.

1 Introduction

Recent research has shown that unobserved components (UC) models can, under certain conditions, be estimated without imposing the common zero-correlation restriction between the permanent and transitory innovations (Morley, Nelson, and Zivot, 2003, hereafter MNZ). Estimates applying this model to U.S. real GDP suggest that U.S. output experiences considerable permanent movements. This result is in stark contrast to the findings based on estimates of zero-correlation UC models which suggest that fluctuations in output are primarily transitory.

This paper develops an unobserved components model that allows for both correlation between all the innovations and asymmetric transitory movements. Extending the correlated UC model to allow for asymmetric transitory movements addresses a key concern about the role of permanent movements in MNZ's results. If the transitory component of U.S. real GDP is asymmetric, in particular having a different mean during recessions as compared to expansions, then MNZ's linear model may over-emphasize permanent movements due to the dominance of expansions in the data. The asymmetry is modeled using Markov-switching in the transitory component, in the spirit of Kim and Nelson's (1999, hereafter KN) version of Friedman's (1993) plucking model.² Importantly, the model allows for correlation not just between the innovations to the permanent and transitory components, but also with the innovation that determines the realization of the Markov-switching state variable.

² Alternative zero-correlation asymmetric unobserved components models include Crespo Cuaresma (2003) and Koopman and Lee (2005). Both of these papers use stochastic trigonometric cycles for the transitory component. Luginbuhl and de Vos (1999) estimate an unobserved components model with Markov-switching in the drift term.

Traditionally, unobserved components models have been estimated assuming that the innovations to the components are uncorrelated. These models, when applied to U.S. output, generally imply smooth permanent components. For example, Clark (1987) estimates a symmetric, zero-correlation unobserved components model of U.S. output and finds that the fluctuations are driven primarily by transitory movements. Using a similar model but relaxing the assumption of symmetry, KN also find a relatively smooth permanent component for U.S. real GDP. The results of their model suggest, however, that U.S. recessions are characterized by *asymmetric* transitory shocks.

In contrast to the results of Clark and KN, MNZ find that output experiences considerable *permanent* movements. MNZ allow for correlation between the innovations to the components and are able to reject the zero-correlation restriction of Clark's model. MNZ's model, however, is symmetric. If recessions, or at least some recessions, are fundamentally different from expansions, then a symmetric model does not properly capture recessions. The idea of asymmetric business cycles has a history back to the beginning of business cycle research (e.g. Mitchell, 1927 and 1951, Burns and Mitchell, 1946, Keynes, 1936, Friedman, 1969; Neftci, 1984). In particular, recessions may be characterized by more transitory movements than found when assuming symmetry. It is also possible that not all recessions are alike, as suggested by Kim and Murray (2002) and French (2005). Some recessions may be characterized by temporary deviations, whereas others may arise due to permanent movements.

There are persuasive economic reasons to generalize MNZ's model to allow for transitory asymmetric shocks. Many economists are more comfortable with positive

permanent shocks than with negative permanent shocks. Permanent shocks are often thought of as arising from improvements in productivity. These shocks may not occur at a constant rate over time (Hamilton, 2005; Friedman, 1993), but economists struggle to explain the “technological regress” needed to justify negative permanent shocks (Fisher, 1932). The difficulty in defending negative permanent shocks has become a popular criticism of the real business cycle literature (Mankiw, 1989). Theoretical and empirical evidence also suggests that the business cycle experiences asymmetric movements, particularly in downturns (see Morley, 2009, for a discussion of this evidence).³ It is important, therefore, to explore the possibility that at least some recessions are driven by temporary asymmetric shocks. If this is the case, then the symmetric estimates of MNZ may over-emphasize permanent movements due to the dominance of expansions in the data, as suggested by MNZ in the conclusion of their article.

To preview the results, the estimates of the asymmetric correlated unobserved components (asymmetric UC-UR) model suggest that allowing for both asymmetry in the transitory component and correlation between the innovations yields estimates from previous models that are different in economically important ways. The transitory asymmetric shocks, although infrequent, are found to be necessary to account for most recessions. Further, the transitory asymmetric shocks appear to be exogenous, suggesting that they arise from a different process than the “normal times” movements in the economy. This result adds to the evidence that recessions are fundamentally different from expansions. The permanent component, however, is still more variable than found

³ For a theoretical model suggesting that asymmetric cycles might arise from intertemporal increasing returns, see Acemoglu and Scott (1997).

based on zero-correlation models. The permanent component captures the majority of output fluctuations, suggesting that expansions, and some recessions, are driven by variable permanent movements. There also remains a symmetric transitory component which is negatively correlated with the permanent innovations and can be interpreted primarily as adjustment to permanent shocks. These results are remarkably robust to structural breaks, including the mean growth slowdown of the early 1970s and the reduction in variance in U.S. real GDP growth around 1984. Extending the sample through 2008 to include the recession that began at the end of 2007, there appears to be important roles for both the permanent component and an asymmetric transitory shock.

This paper proceeds as follows. Section 2 presents the asymmetric UC-UR model and the test for exogeneity of the Markov-switching state variable. Section 3 presents and discusses the results of estimating this model for U.S. real GDP from 1947:1 – 2007:4. Section 4 extends the sample through the end of 2008 to explore implications for the recession that began at the end of 2007. Section 5 provides conclusions and implications.

2 The Model

The model extends the UC-UR model of MNZ to allow for asymmetry in the spirit of Kim and Nelson's (1999) version of Friedman's plucking model. The key features of this model are that it allows for asymmetry in the transitory component via a Markov-switching process,⁴ and at the same time it allows for correlation between all of

⁴ Other models, most notably Hamilton (1989), explore asymmetry in the permanent component. Kim and Piger (2002) show that applying Hamilton's model to data with "plucking"-type recessions results in a potential bias towards permanent movements.

the innovations within the model. Allowing for correlation introduces the possibility of endogeneity if the Markov-switching state variable is also correlated with the other innovations. Thus, as discussed below, this model also allows for endogenous regime switching, building upon the approach of Kim, Piger, and Startz (2008).

Similar to MNZ, output (y_t) can be decomposed into two unobserved components:

$$y_t = \tau_t + c_t \quad (1)$$

where τ represents the permanent (or trend) component and c represents the transitory component.

A random walk for the trend component, as suggested by Friedman (1993), allows for permanent movements in the series. The model also allows for a deterministic drift (μ) in the trend that captures the “tilted” nature of the trend described by Friedman.⁵ The permanent component is written as:

$$\tau_t = \mu + \tau_{t-1} + \eta_t \quad (2)$$

Following MNZ and KN, the transitory component is modeled as an AR(2) process. The novelty of this model, as compared to MNZ, is to include a discrete, asymmetric innovation, γS_t , in the transitory component. The innovation to the transitory component is now a mixture of the symmetric innovation, ε_t , and the asymmetric discrete innovation. This asymmetric innovation captures the “plucks” of Friedman’s plucking

⁵ The unobserved components model of Clark (1987) allowed the drift term to evolve as a random walk. As discussed in Oh and Zivot (2006), the correlations are not all identified if we want to also allow the innovations to the drift term to be correlated with the other innovations. Oh and Zivot (2006) find that the results of MNZ are robust to allowing a random walk drift term in a univariate model. For simplicity, a single known structural break is considered in Section 3.7 to address potentially changing drift.

model, following KN.⁶ The model specifically focuses on this form of asymmetry in the transitory component to explore MNZ’s finding of a small role of the transitory component in general, and during recessions in particular, for U.S. real GDP. The transitory component is written as:

$$c_t = \phi_1 c_{t-1} + \phi_2 c_{t-2} + \gamma S_t + \varepsilon_t \quad (3)$$

The innovations (η_t and ε_t) are assumed to be jointly normally distributed random variables with mean zero and a general covariance matrix, Σ , which allows for correlation between η_t and ε_t .⁷ The model of MNZ is nested as a special case of this model with $\gamma = 0$. With the extended model presented here, the size of γ can therefore be used to test the degree of asymmetry in the transitory component.

The unobserved state variable, S_t , is assumed to evolve according to a first-order Markov-switching process:

$$Pr[S_t = 1 \mid S_{t-1} = 1] = p \quad (4)$$

$$Pr[S_t = 0 \mid S_{t-1} = 0] = q \quad (5)$$

The state of the economy (whether $S_t = 0$ or 1) is thus determined endogenously in the model. For identification of the state variable, it is sufficient to restrict the sign of the discrete, asymmetric innovation (γ). In the case of output, γ is restricted to be non-positive. This restriction forces the more persistent state, that of “normal times,” to have a zero mean. The alternative, i.e. restricting γ to be positive, would result in long periods of positive mean with occasional zero-mean periods. When “normal times” have a zero-

⁶ This model is based on the version of the plucking model presented in Kim and Nelson (1999b).

⁷ Identification of the model is confirmed in a similar fashion to that of MNZ. The basic model is the same as MNZ and is therefore identified. Including Markov-switching adds as many parameters to the reduced form as to the “structural” model, so the model remains identified.

mean transitory component, the permanent component can be usefully interpreted as the steady state, as discussed in Morley and Piger (2009).

To take account of the possible correlation between the state variable and the other innovations, the model includes an extended version of Kim, Piger, and Startz's (2008) endogenous regime-switching model.⁸ Since the state is serially dependent, the lagged state variable can be used as the instrument for the current state, assuming the lagged state variable is exogenous from the contemporaneous error term. The model presented here extends Kim, Piger, and Startz's model to allow the innovation to the latent state variable to be correlated with multiple innovations. The model then allows for an exogeneity test of the state variable as discussed below.

2.1 Exogeneity Test and Bias Correction

Following Kim, Piger, and Startz (2008), the realization of the state process is assumed to be represented using a Probit specification as follows:

$$S_t = \begin{cases} 0 & \text{if } S_t^* < 0 \\ 1 & \text{if } S_t^* \geq 0 \end{cases} \quad (6)$$

$$S_t^* = a_0 + a_1 S_{t-1} + w_t$$

Furthermore, the joint distribution of w_t , η_t , and ε_t is assumed to be multivariate Normal:

⁸ Chib and Dueker (2004) present a non-Markovian regime-switching model with endogenous states in the Bayesian framework that they apply to real GDP growth as in the Hamilton (1989) model. As discussed in Pesaran and Potter (1997), another alternative model would be a threshold autoregression (TAR) model. The application to the plucking model is most straightforward building on the model of Kim, Piger, and Startz, so their method is used here.

$$\begin{bmatrix} w_t \\ \eta_t \\ \varepsilon_t \end{bmatrix} \sim N(0, \Sigma), \quad \Sigma = \begin{bmatrix} 1 & \sigma_{\eta w} & \sigma_{\varepsilon w} \\ \sigma_{\eta w} & \sigma_{\eta}^2 & \sigma_{\eta \varepsilon} \\ \sigma_{\varepsilon w} & \sigma_{\eta \varepsilon} & \sigma_{\varepsilon}^2 \end{bmatrix}$$

However, in the special case where the state variable is exogenous, w_t is uncorrelated with η_t and ε_t :

$$\begin{bmatrix} w_t \\ \eta_t \\ \varepsilon_t \end{bmatrix} \sim N(0, \Sigma_1), \quad \Sigma_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \sigma_{\eta}^2 & \sigma_{\eta \varepsilon} \\ 0 & \sigma_{\eta \varepsilon} & \sigma_{\varepsilon}^2 \end{bmatrix}.$$

In this case the expectation of $\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix}$, conditional upon S_t , S_{t-1} , and I_{t-1} (the information

available at time $t-1$) is zero. Similarly, the conditional variance for $\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix}$ is equal to the

unconditional variance:

$$E\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \mid S_t = i, S_{t-1} = j, I_{t-1}\right) = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

and

$$\text{var}\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \mid S_t = i, S_{t-1} = j, I_{t-1}\right) = \begin{bmatrix} \sigma_{\eta}^2 & \sigma_{\eta \varepsilon} \\ \sigma_{\eta \varepsilon} & \sigma_{\varepsilon}^2 \end{bmatrix}.$$

In the case of endogenous switching, however, either $\sigma_{\eta w}$ and/or $\sigma_{\varepsilon w}$ does not equal zero.

Thus the conditional mean and variance-covariance matrix become:

$$E\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \middle| S_t = i, S_{t-1} = j, I_{t-1}\right) = \begin{bmatrix} \sigma_{\eta w} M_{ij} \\ \sigma_{\varepsilon w} M_{ij} \end{bmatrix}$$

and

$$\text{var}\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \middle| S_t = i, S_{t-1} = j, I_{t-1}\right) =$$

$$\begin{bmatrix} \sigma_{\eta}^2 - \sigma_{\eta w}^2 M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) & \sigma_{\eta \varepsilon} - \sigma_{\eta w} \sigma_{\varepsilon w} M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) \\ \sigma_{\eta \varepsilon} - \sigma_{\eta w} \sigma_{\varepsilon w} M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) & \sigma_{\varepsilon}^2 - \sigma_{\varepsilon w}^2 M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) \end{bmatrix},$$

where

$$M_{00} = \frac{-\phi(-a_0)}{\Phi(-a_0)}$$

$$M_{01} = \frac{-\phi(-a_0 - a_1)}{\Phi(-a_0 - a_1)}$$

$$M_{10} = \frac{\phi(-a_0)}{1 - \Phi(-a_0)}$$

$$M_{11} = \frac{\phi(-a_0 - a_1)}{1 - \Phi(-a_0 - a_1)}.$$

ϕ is the standard normal probability density function and Φ is the standard normal cumulative distribution function. a_0 and a_1 come from the equation for S^* in (6) above.

The exogenous switching model is nested within the endogenous switching model with the restriction that $\sigma_{\eta w} = \sigma_{\varepsilon w} = 0$. This nesting allows for a simple test of exogeneity with a likelihood ratio test comparing the endogenous model with the restricted exogenous model. The results of this test are discussed in Section 3.1.

3 Empirical Results

The data (y) are the natural log of U.S. real GDP multiplied by 100, quarterly, from 1947:1 – 2007:4.⁹ To estimate the model presented in the previous section, it is cast into state-space form, available in the appendix. Kim's (1994) method of combining Hamilton's algorithm and a nonlinear discrete version of the Kalman filter is then used for an approximation to maximum likelihood estimation of the parameters and the components.¹⁰ If the state variable is endogenous, the regime-dependent conditional density function is no longer Gaussian (see discussion in Kim, Piger, and Startz; 2008). Assuming the density function is Gaussian results in quasi-maximum likelihood estimation.

3.1 Testing for Exogenous Markov-Switching

First we must determine whether the Markov-switching is exogenous or endogenous. Estimating the endogenous Markov-switching UC-UR model for U.S. real GDP results in a log likelihood value of -314.2, whereas the restricted model of exogenous switching has a log likelihood value of -315.8. Thus, the likelihood ratio test statistic is 3.2 and the null hypothesis of exogenous switching cannot be rejected at conventional significance levels with a p-value of 0.2.¹¹ Importantly, the estimates are qualitatively similar whether we allow for endogenous switching or restrict the model to exogenous switching. This result suggests that the discrete, asymmetric shocks are due to

⁹ The data come from the FRED database at the Federal Reserve Bank of St. Louis. They are in billions of chained 2000 dollars, seasonally adjusted annual rate. The results for an updated sample through the end of 2008 will be discussed in Section 4.

¹⁰ To ensure that the estimates represent the global maximum, estimates of all models were repeated using different starting values approximating a course grid search.

¹¹ Likelihood ratio test statistics will be used for hypothesis testing throughout this paper for robust inference in the face of potential weak identification following Nelson and Startz (2007).

a different process than the other shocks that affect output. Furthermore, this result provides support for previous research on U.S. aggregate output which assumed that the Markov-switching was exogenous (e.g. research building on the model of Hamilton, 1989). Finally, the finding that the asymmetric shock is uncorrelated with the permanent innovation suggests that there is no residual asymmetry in the permanent component. Based on this result, the rest of the discussion will focus on the estimates using exogenous Markov-switching, which are presented in the first column of Table 1.

3.2 Testing for Asymmetry

Including the asymmetric transitory shock appears to represent an improvement over the symmetric UC-UR model, as shown in Table 1, comparing columns (1) and (2). Testing the restriction of a symmetric model, i.e. that $\gamma = 0$, the likelihood ratio test statistic is 29.8. This test statistic, however, is nonstandard. In order to establish the statistical significance of this result, a parametric bootstrap test was performed.¹² Data were simulated under the null of no asymmetry, i.e. using the parameter estimates of the symmetric UC-UR model from column 2 of Table 1. The model was re-estimated for each sample under both the null and the alternative to obtain a likelihood ratio test statistic.¹³ The bootstrapped p-value, based on 999 bootstrap samples, is 0.01. This suggests that asymmetry is indeed important for explaining the movements in U.S. real GDP.

¹² See MacKinnon (2002, 2006) for summaries of bootstrap methods.

¹³ Di Sanzo (2007) shows that a bootstrap of a likelihood ratio test statistic performs well for testing linearity in Markov Switching models.

3.3 Testing for Correlation

Including the asymmetric transitory component does not eliminate the correlation between the innovations to the permanent component and the symmetric transitory component. Comparing columns (1) and (3) of Table 1 shows that the restriction of zero correlation between the permanent and symmetric transitory innovations for the asymmetric model (the asymmetric UC-0 model) is rejected, with a p-value for the likelihood ratio test statistic of 0.01. Allowing for correlation between the permanent and symmetric transitory innovations results in more permanent movements than if a zero-correlation restriction were imposed as in KN's model (note the higher standard deviation of the permanent innovation in the correlated case in column (1) of Table 1 as compared to column (3)).

KN further find evidence that for U.S. real GDP there is no symmetric shock to the transitory component once they allow for the discrete, asymmetric shock. Here, however, the symmetric innovation remains important and retains its interpretation from MNZ as an adjustment to permanent shocks. Restricting the variance of the symmetric transitory innovation as well as the correlation between this innovation and the permanent innovation to both be zero results in a log likelihood value of -319.2420. We can therefore reject the restrictions with a p-value of 0.03. Note that this log likelihood value is only slightly smaller than the log likelihood for the asymmetric UC-0 case, thus confirming KN's result. If the correlation between the innovations is restricted to zero, then the symmetric transitory shock is not statistically significant. However, again, the restriction that the correlation can be zero is rejected by the data.

3.4 The Estimated Components of U.S. Real GDP

Panels 1 and 2 of Figure 1 present the filtered estimates of the unobserved components of output based on the exogenous Markov-switching asymmetric UC-UR model. The filtered estimates are used instead of the smoothed estimates because including Markov switching results in smoothed estimates requiring successive approximations, as discussed in KN. These estimates appear to be a hybrid of the symmetric correlated model and the zero-correlation plucking model, as can be seen in Figure 2. The permanent component is more variable than in the zero-correlation case (with the standard deviation of the permanent innovation being more than 1.5 times the size), but there is also more transitory movement, particularly near NBER recession dates, than was found by MNZ.

The difference in the transitory components between the MNZ model and the asymmetric UC-UR model is not due to the symmetric innovation or to the AR parameters, which are similar in the two models. The difference arises due to the inclusion of the asymmetric shock, resulting in movements in the transitory component for the asymmetric UC-UR model between -6.13 to 0.67 , whereas the symmetric UC-UR transitory component ranges in value from -1.66 to 1.65 .

Including asymmetry in the transitory component results in movements which look much more like Friedman's plucking model than the transitory component of the symmetric UC-UR model. In particular, the transitory component appears to move in general with the business cycle, as indicated by the shaded NBER recession dates. These results are similar to the findings of Morley and Piger (2009) who use a generalization of

the Beveridge-Nelson (1981) decomposition for processes in which both trend and cycle can be regime switching (based on Morley and Piger 2008).¹⁴ This similarity should not be surprising since MNZ show that in the symmetric case, a correlated unobserved components model produces the same estimated components as the Beveridge-Nelson (1981) decomposition for the same forecasting model. Morley and Piger's approach, combined with the 'bounce-back' model of Kim, Morley, and Piger (2005) allows regime switches into recessions to have permanent and/or transitory effects, but they find that regime switches have largely transitory effects, as is assumed here.¹⁵

Even though Panel 1 of Figure 2 looks more like Panel 3 than Panel 2, there are also important differences due to the allowance of correlation. The estimates of the asymmetric UC-UR model suggest that each recession differs in terms of the contribution of permanent and transitory movements. These results are similar to the results from Kim and Murray's (2002) multivariate model of monthly indicators. They specifically allow for there to be differences in the role of permanent versus transitory movements for different recessions and find that each recession indeed differs. In particular, rather than finding that all recessions are characterized by asymmetric transitory movements, Panel 1 suggests that only six out of the last ten recessions are clearly characterized by transitory movements. The two types of recessions will be discussed further in Sections 3.5 and 3.6.

¹⁴ Clarida and Taylor (2003) also extend the Beveridge-Nelson decomposition to nonlinear processes. They apply their methodology to US GNP using the Beaudry and Koop (1993) form of nonlinearity. They show that estimates of their nonlinear model appear to better match the NBER-dated peaks and troughs as compared to linear models.

¹⁵ Kim, Morley, and Piger (2005) find that allowing for an asymmetric 'bounce-back' effect results in a much smaller permanent effect of recessions as compared to Hamilton's (1989) model.

The asymmetric shocks only occur occasionally, so they do not explain a large amount of the variance of the series, but they are large and significant. The estimated variances of the innovations to the permanent and transitory components from the asymmetric model are not significantly different from those of the symmetric model (the no switching estimate in Table 1 column (2)). Based on the estimates of p and q presented in column (1) of Table 1, the expected duration of State 1 (i.e. when the mean of the transitory component is negative) is approximately 3.5 quarters, whereas the expected duration of State 0 is almost 32 quarters. Other research has also found that transitory movements may only explain a small, but important, portion of the variance of U.S. real GDP. Using an innovation regime-switching model, Kuan, Huang, and Tsay (2005) conclude that unit-root nonstationarity dominates in almost 85% of the sample periods, with 33 stationary periods that closely match the NBER dating of recessions.

One movement which appears in the symmetric transitory component (and also in the permanent component due to the negative correlation) deserves some attention. From 1978:2 to 1979:1, we observe the largest symmetric transitory movement in the sample. At first glance, this movement, as seen in Panel 2 of Figure 1, may appear to be due to an asymmetric transitory shock, but Panel 3 shows that there is at most a probability of 0.1 of such a shock for this time period. Panel 1 also shows that at this point in the sample the permanent component appears to spike away from the series. Forecasters predicted that due to the oil shock in 1978, there should follow a recession analogous to the recession following the 1973 oil shock. The brief permanent movement above the series may perhaps be explained by changes in consumer behavior in response to the oil shock

(Goldfarb, Stekler, and David, 2005). The movement in the transitory component shows simply that the series did not adjust immediately to the permanent movement, resulting in the transitory gap between the permanent component and the series.

3.5 The “Pluck” Recessions

Although rare, the asymmetric shocks appear important in a few key episodes. These episodes are represented in Panel 3 of Figure 1. This panel presents the probabilities of asymmetric shocks to the transitory component of real GDP. There is some positive probability of a transitory asymmetric shock for all of the NBER-dated recessions, with six of the ten recessions in the sample having probability greater than 0.5. Figure 1 shows that for the recessions characterized by asymmetric shocks the series drops below the permanent component. These recessions have the appearance of a pluck as described by Friedman such that the permanent component appears to be a ceiling and the series is temporarily “plucked” away from that ceiling. As discussed by Friedman (1993) and KN, models that emphasize monetary or other demand-oriented shocks may be more appropriate for explaining these recessions.

3.6 The “No-Pluck” Recessions

The no-pluck recessions appear to represent a different type of recession from those characterized by asymmetric shocks. The four recessions where the probability of an asymmetric transitory shock remains below 0.5 are 1969:4 – 1970:4, 1973:4 – 1975:1, 1990:3 – 1991:1, and 2001:1 – 2001:4. For these recessions, the movement is in general largely permanent, as can be seen in Figure 1. In fact, for the 2001 recession, the transitory component remains positive for the entire recession. In the other three

recessions without asymmetric shocks, however, there is a noticeable peak-to-trough movement in the transitory component, but it is smaller in general than in the recessions that experienced asymmetric shocks.

The recession which occurred in 1973:4 – 1975:1 appears quite close to the cutoff with a probability of 0.44. The remaining three no-pluck recessions were classified by Koenders and Rogerson (2005) as the three recessions characterized by jobless recoveries. These recessions therefore appear to have different features than the “pluck” recessions. In addition, for the 1969 – 1970 and 1990 – 1991 recessions, forecasters had particular difficulty predicting them, as discussed in Enzler and Stekler (1971) and Fintzen and Stekler (1999). Since the permanent component captures the unpredictable movements of the series, it is not surprising that these two recessions appear to be largely captured by the permanent component. Kim and Murray (2002) and French (2005) also find that the 1990-91 recession does not appear as a transitory movement. The 1973 – 1975 recession is often characterized as caused by a permanent shock due to the behavior of OPEC at the time.¹⁶ Finally, for the 2001 recession, other econometric models also find that this recession looks different than other recessions (e.g. Kim, Morley, and Piger, 2005, and French, 2005), perhaps because it was particularly mild.

3.7 Robustness Checks

Two possible structural changes in U.S. real GDP need to be examined more carefully before accepting the results of this model. First, there may have been a

¹⁶ The other “oil-shock” recession in 1979-1980 does appear to be characterized by an asymmetric transitory shock. Abel and Bernanke (2005, page 326) argue that people expected the oil shock of 1973 – 1975 to have permanent effects, but expected the shock of 1979 – 1980 to only have temporary effects. They note as evidence that the real interest rate rose in 1979 – 1980 whereas in 1973 – 1974 it did not. Friedman (1993) suggests that oil shocks may also be asymmetric shocks.

structural break in the drift term of the permanent component in the early 1970s (Perron, 1989, and Perron and Wada, 2006). Second, GDP growth experienced a significant volatility reduction in 1984, otherwise known as the Great Moderation (Kim and Nelson, 1999c, and McConnell and Perez-Quiros, 2000). This section presents evidence that the results of this model are robust to allowing for these changes in U.S. real GDP. Most importantly, the finding of which recessions are “pluck” recessions does not change with any of these changes to the model.

3.7.1 Structural Break in the Drift Term

Including a structural break in the drift term (μ) in 1973, Perron and Wada (2006), show that the results for MNZ’s symmetric model change significantly. In particular, the estimated permanent component of U.S. real GDP reduces to a deterministic trend with a single structural break. Table 2 presents estimates including a structural break in the drift term in 1973, and shows that the results of the asymmetric UC-UR model are robust to this break. In fact, in the asymmetric model the restriction of no structural break in the drift term of the permanent component is not rejected at the 5% level. A break in γ , the size of the asymmetric shock, (along with a break in the drift term) in 1973 was also found to be insignificant with no qualitative difference in the results. Furthermore, testing for a structural break at an unknown date between 1965 and 1975 found no significant break dates based on the test given in Andrews (1993). Finally, searching for a joint break in the drift term and the size of the asymmetric shock at the same time did not change these results. These results suggest that once the asymmetry in the transitory

component is taken into consideration, the role of a structural break in the drift term is greatly diminished.

3.7.2 The Great Moderation

Table 3 presents the estimates allowing for a structural break in the covariance matrix in the first quarter of 1984 to capture the reduced volatility in the growth rate of U.S. real GDP known as the Great Moderation.¹⁷ This break is statistically significant, but it does not change any of the main results or figures presented in the previous sections, nor does it significantly affect parameters other than those in the covariance matrix.

The estimated elements of the covariance matrix are, however, independently interesting. Previous research has primarily focused on the reduction in the volatility of the growth rate of GDP (starting with Kim and Nelson, 1999c, and McConnell and Perez-Quiros, 2000). The estimates presented in Table 3 show the change in the standard deviation of the permanent innovation, the standard deviation of the temporary innovation, and the correlation between the two innovations. The volatility reduction appears for both the permanent and transitory innovations. The post-1983 variance of the permanent component is less than 85% of the pre-1984 variance. The post-1983 variance of the transitory component is less than 70% of the pre-1984 variance. The correlation parameter, however, increased in absolute value after 1983. This change in the correlation may be interpreted either as an increase in the importance of adjustments to

¹⁷ See Stock and Watson, 2002, for a discussion of the evidence and the potential explanations for the Great Moderation.

permanent movements in driving the transitory innovations after 1983, or equivalently as a decrease in the importance of other transitory shocks.

Estimating a model allowing for a break in the size of the shock in 1984 (with or without also allowing for a change in the covariance matrix) results in an asymmetric model before 1984, but reduces to the symmetric MNZ model post-1983. These results are thus similar to the full sample estimates which also find no asymmetric shocks after 1983, based on a cutoff probability of 0.5. Estimating the full model with only the 1947:1 – 1983:4 sample also resulted in estimates that are remarkably similar to the full sample results. These results are similar to Kim (2008) who finds that U.S. output persistence has increased since 1984 due not to a change in autoregressive parameters but rather because recessions post-1984 appear to be characterized by permanent movements.

4 Exploring the Recession that began in 2007

According to the NBER Business Cycle Dating Committee, another recession began for the U.S. in the fourth quarter of 2007. As of this writing, three questions arise when updating the dataset to include data for 2008: 1) Will the information from the current recession change our view of recessions more generally? 2) Will the current recession appear to be a “pluck” recession? 3) If it is a “pluck” recession, when will the model identify to be the beginning of the “pluck”? Two caveats must also be mentioned when exploring these further results. First, although the data released for 2008 by the Bureau of Economic Analysis (BEA) are called “final” in the BEA’s terminology, they

have not yet undergone the annual revisions that occur each year in July.¹⁸ Therefore, these data are subject to further revision as compared to the dataset through 2007. Second, the current recession does not yet appear to have ended, so results may change dramatically with future information on the anticipated recovery.

Despite the caveats, the current recession (as of this writing) is clearly an interesting application of this model. Therefore, Figure 3 presents the updated probabilities of exogenous asymmetric shocks when we include the 2008 data. As can be seen by comparing Figure 3 with Panel 3 of Figure 1, the addition of the 2008 data does not change our inferences about the prior recessions based on the estimates through 2007. In fact, all of the parameter estimates are quantitatively and qualitatively similar to those for the model estimated through 2007 both with and without the structural breaks discussed previously.

What is perhaps more interesting is to explore the inferences regarding the current recession. The probabilities presented in Figure 3 suggest that a “pluck” recession began in the fourth quarter of 2008. This dating is quite specific according to the model with probabilities of a pluck in the first three quarters of 2008 all being less than 0.05, but the probability rises to 0.84 for the fourth quarter. These results suggest that the first part of the current recession could be characterized as a “no-pluck” recession, with the “pluck” aspect of this recession beginning in the fourth quarter of 2008. This is illustrated in Figure 4 where the permanent component drops below the real GDP series in the fourth

¹⁸ In addition, in July 2009 the BEA will perform a benchmark revision of the national income and product accounts (NIPAs). The last comprehensive revision was released in December 2003. For a discussion of how this may change the GDP data, see Seskin and Smith (2009).

quarter of 2007 and then the series plunges below the permanent component as we move into the fourth quarter of 2008. If this recession follows historical patterns, the model suggests that the transitory part of the recession will be over in approximately 3.5 quarters.

5 Conclusions

This paper has developed and estimated an unobserved components model, the asymmetric UC-UR model, which is a generalization of Morley, Nelson, and Zivot's (2003, MNZ) correlated unobserved components model, allowing for asymmetry. This model allows for correlation between the innovations to the components as well as for asymmetry in the transitory component. The asymmetry is modeled using Markov-switching in the transitory component in the spirit of Kim and Nelson's (1999, KN) version of Friedman's (1993) plucking model. The results suggest there exists a ceiling of maximum feasible output that is well-approximated by a random walk, but that occasionally (for at least seven of the last eleven U.S. recessions), output is "plucked" away from this ceiling by an exogenous transitory shock. In particular, the recession that began December of 2007 according to the NBER business cycle dating committee appears to be characterized by a "pluck" beginning in the fourth quarter of 2008.

The estimates of the asymmetric UC-UR model suggest that allowing for both correlation and asymmetry yields considerably different results from both the symmetric correlated unobserved components model of MNZ and the asymmetric uncorrelated unobserved components model of KN. The permanent component is more variable than in the zero-correlation case, but there is also more transitory movement, particularly near

NBER recession dates, than was found by MNZ. Further, the transitory asymmetric shocks appear to be exogenous, suggesting that they are due to a different process than the “normal times” movements in the economy. There remain, however, significant permanent movements in the series, and the permanent innovations are negatively correlated with the symmetric transitory innovations. These results are robust to allowing for structural breaks to control for the mean growth slowdown of the early 1970s as well as for the variance reduction in 1984.

The results presented here suggest that exogenous transitory shocks may be important for most recessions, but that U.S. real GDP experiences more permanent movements than what might be expected based on conventional business cycle models. These results indicate that there may be different types of recessions with different underlying causes. These different causes may have important policy implications.¹⁹ In particular, this paper adds to the growing research arguing that policy should take into consideration the importance of asymmetric shocks. As discussed by De Long and Summers (1988), the presence of asymmetric shocks suggests that policy addressed at reducing these shocks may be able to lessen the impact of recessions without reducing peaks. Policy could thus increase the average level of output, rather than just reduce its volatility.

¹⁹ One possible research agenda to follow would be to consider the suggestion of Hamilton (2005) that the volatility of interest rates may play an important role in causing asymmetric shocks. He finds that many, but not all, economic downturns are accompanied by a change in the dynamic behavior of short-term interest rates. Another reasonable direction to follow is to try to determine if the asymmetric shocks are monetary, as suggested by Friedman (1993).

Appendix: State Space Form

In state-space form the series can be represented as follows:

$$\text{Observation Equation: } [y_t] \equiv \begin{bmatrix} 1 & 1 & 0 \end{bmatrix} \begin{bmatrix} \tau_t \\ c_t \\ c_{t-1} \end{bmatrix}.$$

$$\text{State Equation: } \begin{bmatrix} \tau_t \\ c_t \\ c_{t-1} \end{bmatrix} = \begin{bmatrix} \mu \\ \gamma S_t \\ 0 \end{bmatrix} + \begin{bmatrix} 1 & 0 & 0 \\ 0 & \phi_1 & \phi_2 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \tau_{t-1} \\ c_{t-1} \\ c_{t-2} \end{bmatrix} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix}.$$

Variance-Covariance Matrix:

In the case of exogenous switching:

$$E\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \begin{bmatrix} \eta_t & \varepsilon_t \end{bmatrix}\right) = \begin{bmatrix} \sigma_\eta^2 & \sigma_{\eta\varepsilon} \\ \sigma_{\eta\varepsilon} & \sigma_\varepsilon^2 \end{bmatrix}.$$

In the case of correlation between the state variable and the other innovations the variance-covariance matrix becomes:

$$\text{var}\left(\begin{bmatrix} \eta_t \\ \varepsilon_t \end{bmatrix} \mid S_t = i, S_{t-1} = j, I_{t-1}\right) = \begin{bmatrix} \sigma_\eta^2 - \sigma_{\eta w}^2 M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) & \sigma_{\eta\varepsilon} - \sigma_{\eta w} \sigma_{\varepsilon w} M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) \\ \sigma_{\eta\varepsilon} - \sigma_{\eta w} \sigma_{\varepsilon w} M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) & \sigma_\varepsilon^2 - \sigma_{\varepsilon w}^2 M_{ij} (M_{ij} + a_0 + a_1 S_{t-1}) \end{bmatrix}$$

where a_0 and a_1 come from the equation for S^* in equation (6) from Section 2.1 and the M_{ij} are also defined as in Section 2.1.
